INTRODUCTION
Bronchiectasis (B) is a chronic inflammatory lung disease characterized by recurrent cough, sputum production, and recurrent airway infections [1]. Previously B considered as a rare or orphan disease, but now the prevalence has been reported up to 566 per 100,000 population, moreover, over the past 10 years the incidence has been enlarged by 40% [2]. The common pathophysiological pathway of B consists of Cole’s “vicious cycle” hypothesis of infection, inflammation and airway structural changes [3]. Exacerbations of B defined clinically as worsening of the usual respiratory symptoms (sputum quantity, sputum purulence, or dyspnea) requiring treatment with antibiotics [4, 5]. They are associated with accelerated lung function decline and deterioration in quality of life [6]. Exacerbations are important events in the natural history of B and their management imposes a significant economic burden on the healthcare system. Patients with three or more exacerbations a year had worse health status, were more likely to be hospitalized for treatment, and had increased mortality [7]. Published data suggest that the number of exacerbations per year independently predicts future risk of mortality [8], while patients with three or more exacerbations per year have double mortality rate compared to those who do not experience exacerbations [9]. Thus, B exacerbations are both an indicator of severity and a driver of disease progression, but a great deal more data are needed to fully understand their causes and consequences [10]. In clinical practice, it is important to identify patients who are at risk of future exacerbations to plan preventative therapy appropriately [11]. International guidelines for B recommend treatment with, for example, inhaled or oral prophylactic antibiotic therapy for patients with three or more exacerbations per year to prevent worsening of the clinical symptoms [12, 13], but at this time point, the evidence background is quite small. To date, the relationships between the frequency of exacerbations and chronic colonization of Pseudomonas aeruginosa (PA) [14], as well as high neutrophil elastase activity [15], an elevated level of cathelicidin LL-37 and reduced Secretory Leukocyte Protease Inhibitor levels [16] are described in the frequent exacerbator phenotype. Low forced expiratory volume in the first second (FEV1), radiological severity of disease and coexisting chronic obstructive pulmonary disease are also described as independent predictors of future exacerbation frequency [10]. Searching for other specific markers, which could predict the risk of exacerbations, is still in progress [17].

THE AIM
The study aimed to determine which other specific factors could predict the risk of B exacerbations.

FACTORS AFFECTING THE FREQUENCY OF EXACERBATIONS IN ADULT PATIENTS WITH BRONCHIECTASIS

MATERIALS AND METHODS

STUDY POPULATION
Patients with B were prospectively recruited into the study in Dnipropetrovsk region in Department of Occupational Diseases and Clinical Immunology of State Establishment “Dnipropetrovsk medical academy of the Ministry of Health of Ukraine” from October 2018 to July 2019. Inclusion criteria: adult males and females with B confirmed by high resolution computed tomography (HRCT) based on the following criteria: 1) lack of tapering within the bronchi; 2) dilation of the bronchi wherever the inner diameter was larger than that of the adjacent pulmonary artery, or 3) visualization of the peripheral bronchi at intervals one centimeter of the costal pleural surface or the adjacent mediastinal pleural surface [18]. Stable phase of B (no change in symptoms and medication for at least 8 weeks) was required. Exclusion criteria: cystic fibrosis, active tuberculosis, history of any malignancy, pregnancy and lactation, history of lung transplantation.

STUDY GROUP
47 patients (caucasians) were enrolled in the study. Most of them were women ($p = 0.003$), mostly non-smokers ($p = 0.001$), more than half had signs of airway obstruction ($p = 0.024$). Depending on the number of exacerbations per previous year, patients were divided into two groups: frequent exacerbators - $\geq 3$ cases per year ($n = 24$) and non-frequent exacerbators - $< 3$ cases per year ($n = 23$).

METHODS
Demographic and anthropometric data of all patients were registered: gender, age, height by the stadiometer RP-2000, weight using the scales “Body composition monitor Omron

**Fig. 1.** Detected pathogens in the sputum of Frequent exacerbators (group 1).

**Fig. 2.** Detected pathogens in the sputum of non-Frequent exacerbators (group 2).
BF511” for the static weighing. Body mass index (BMI) was calculated by the conventional formula [19]. Medical history (duration of the disease from the moment the diagnosis is confirmed, frequency of exacerbations during the previous year and hospital admissions during the previous 12 months, presence of comorbidity) was detected in medical source documentation. Smoking status was self-reported. Dyspnea was assessed using the Modified Medical Research Council Dyspnea Scale [20].

Sputum samples were accepted if they contained < 10 squamous epithelial cells per low-powered field. Microbiological detection of sputum samples was conducted by conventional bacteriological methods [21]. In most cases we examined spontaneous sputum (n=40), in cases where the patients did not produce sputum, we examined induced sputum (n=7).

For all patients baseline, the respiratory function was measured by computed spirometry using the MasterLab (Viasis, Germany). Post-bronchodilation tests were evaluated in 15 minutes after administration of 400 μg of salbutamol by pressurized metered-dose inhaler via a spacer. Predicted and absolute values of FEV1, forced vital capacity (FVC) and FEV1/FVC ratio were calculated by ATS and ERS 2005 standards. Blood oxygen saturation (SpO2) was measured in sitting patients after a 30-minute rest by pulse oximeter Bitmos Sat 816 Masimo SET.

The severity of the disease was determined using Bronchiectasis Severity Index (BSI), which consisted of age, BMI, HRCT score (independent predictor of future hospitalization was three or more lobes involving), FEV1, Medical Research Council dyspnea score, bacterial colonisation (PA or other pathogenic bacteria), prior hospital admission and exacerbations (3 or more exacerbations are suggested as independent predictor of mortality and future hospitalizations) [22] and using FACED score, which comprises FEV1 (F), age (A), PA colonization (C), radiological extension (E) (two or more lobes involving suggested as significant value) and dyspnea (D) [23].

STATISTICS
Statistical analyses were performed using the «STATISTICA 6.1» (StatSoft Inc., USA, № AGAR909 E415822FA). The data were presented as mean (standard deviation, SD) and median (interquartile range, IQR) in the case of quantitative variables, or as absolute numbers and percentages (n, %) in the case of qualitative variables. The distribution of variables was analysed using the Shapiro-Wilk test. The Chi-squared test was used to test the differences in discrete variables. Whereas for continuous variables, the t-test or Mann-Whitney U test was used. Spearman’s coefficient was calculated to assess the correlation between variables. The 95 % confidence interval was calculated for the independent variables, with p ≤ 0.05 considered to be significant.

Authors declare that the research was conducted according to the principles of the World Medical Association Declaration of Helsinki “Ethical Principles for Medical Research Involving Human Subjects” (amended in October 2013). Approvals were obtained from the ethics committee of the State Establishment “Dnipropetrovsk medical academy of the Ministry of Health of Ukraine”. Written informed consent was obtained from all patients who participated in this study.

RESULTS AND DISCUSSION
Demographic, anthropometric and clinical characteristics of the patients are presented in table 1.

Both groups were similar by age, sex and smoking status, no correlation was found between the number of exacerbations and age (R = 0.1, p = 0.48), sex (R = 0.02, p = 0.88), smoking status (R = -0.19, p = 0.19).

Patients with increased BMI prevailed in the total sample. The average BMI was statistically significantly higher in the group of frequent exacerbators, in addition, the proportions of overweight patients were also significantly higher in the group of frequent exacerbators and there was a direct correlation between the number of exacerbations and BMI (R = 0.39, p = 0.006). The duration of the disease was statistically different too — frequent exacerbators were sick much longer at the time of the study, also direct correlation between disease duration and exacerbation frequency was detected (R = 0.43, p = 0.003). More than half of the patients had a history of hospitalization for B, however, there was a significantly higher hospitalization rate among frequent exacerbators. Non-frequent exacerbators assessed their dyspnea by the mMRC less severe than frequent exacerbators, the correlation between shortness of breath by the mMRC and exacerbation number was direct (R = 0.48, p = 0.003).

Almost all patients in both groups had normal FVC, however, frequent exacerbators more often had signs of airways obstruction, including significantly lower values of FEV1 and FEV1/FVC ratio. Analysis of FEV1 values in patients with reduced FEV1/FVC ratio revealed that among non-frequent exacerbators the first stage of obstruction prevails, unlike frequent exacerbators among whom 72.4 % of patients have obstruction of the second stage and higher. There was found negative correlation between exacerbation frequency and FEV1, R = - 0.39, p = 0.005, and FEV1/FVC ratio, R = - 0.47, p = 0.0008).

SpO2 was normal in almost all patients, but the comparison of the values showed that among the frequent exacerbators SpO2 was statistically lower.

The number of involved lung lobes is one of the main criteria for calculating the severity of B according to both BSI and FACED scales. The patients in both groups on average had two or more affected lobes and the difference in the number of involved lobes between two groups was not statistically significant. However, the correlation between exacerbation frequency and number of involved lobes was identified (R = 0.37, p = 0.013).

As for sputum microbiota, pathogens were detected in 31 (66 %) samples. The most common pathogens were Pseudomonas aeruginosa and Haemophilus influenzae in both groups. The proportions of detected pathogens in groups...
FACTORS AFFECTING THE FREQUENCY OF EXACERBATIONS IN ADULT PATIENTS WITH BRONCHIECTASIS

The population of patients with B in Dnipro region is mainly people of working age, more often women. We found out that such factors as age, sex and history of smoking do not affect the frequency of exacerbations in these patients. Unexpectedly our study showed, that the presence of pathogens in sputum, in particular, PA also is not a statistically significant predictor of more frequent exacerbations. Perhaps this may be due to the fact that such patients are more likely to suffer from a productive cough with purulent sputum, due to which, in turn, it is difficult for them to determine the exacerbation. While patients without PA colonization are easier to independently determine the exacerbation and seek medical help.

At the same time, we discovered that overweight even more than underweight can be an independent predictor of more frequent exacerbations. In our study frequent exacerbators had a longer duration of the disease from the moment the diagnosis was confirmed, more severe dyspnea and airways obstruction, lower blood oxygen saturation and more severe disease by BSI than non-frequent exacerbators. Furthermore, the number of exacerbations increased with the number of affected lung lobes and correlated with the presence of respiratory or non-respiratory comorbidity. So exactly these factors could be proposed to consider as predictors of frequent exacerbations in adult patients with bronchiectasis.
