INTRODUCTION
The suspicion of pulmonary hypertension (PH) is based on classic clinical symptoms and echocardiographic features that may indicate the disease. For example, transthoracic echocardiography (TTE) is used to assess the likelihood of PH and to evaluate treatment outcomes. However, echocardiographic examination alone is not sufficient to make a diagnosis of PH, for which a right heart catheterization is required. Still, echocardiographic assessment of the right ventricular (RV) is a part of routine echocardiography and detailed guidelines describing this evaluation can be found in a document issued by the American Society of Echocardiography (ASE) and the European Association of Cardiovascular Imaging (EACVI) in 2015 [1].

THE AIM
The aim of the study is to determine the significance of echocardiography in the diagnostic process, prognosis and evaluation of treatment effectiveness in pulmonary hypertension.

REVIEW AND DISCUSSION
According to the ESC/ERS Guidelines for the Diagnosis and Treatment of Pulmonary Hypertension 2015, it is recommended to use maximum tricuspid regurgitation wave velocity (TRVmax), estimation by continuous wave Doppler as the main parameter in assessing the probability of PH. Unfortunately, despite the strong correlation between TRV and the right ventricle and the systolic pressure gradient between right ventricle and right atrium (RA), pressure as established by means of Doppler measurements may be inaccurate in individual patients (e.g. patients with severe tricuspid valve regurgitation). Therefore, attention should be paid to other echocardiographic features that may enhance PH suspicion. Thus, to determine the probability of PH, several additional echocardiographic parameters have been proposed. These include RV dimensions assessment, signs of RV pressure overload, RV ejection time, pulmonary artery (PA) diameter and estimated right atrial pressure (RAP). On the basis of echocardiography, the probability of low, intermediate and high PH can be determined [2].

In echocardiographic evaluation, it is extremely important to standardize methodology, as allowed by the knowledge of relevant recommendations. Echocardiographic techniques are constantly evolving, especially real-time three-dimensional echocardiography (3DE) and myocardial deformation imaging [1, 4].

The evaluation of RV dimensions and functions is complex due to its compound geometry, position just behind the sternum and the different systolic mechanism than that of the left ventricle. What is more, the right ventricle is wrapped around the left ventricle and its shape is described as a triangular pyramid [3] RV imaging should
be performed using multiple acoustic windows and the assessment should include both quantitative and qualitative parameters. Among the parameters, which should be measured are right ventricular and right atrial dimensions, as well as right ventricular systolic function assessment, using one or a combination of the following: tricuspid annular plane systolic excursion (TAPSE), DTI-derived tricuspid lateral annular systolic velocity wave (S’), fractional area change (FAC) and RV index of myocardial performance (RIMP) [1, 3].

Additional measurements, such as RV volume and ejection fraction EF using 3 DE, can complement the above 2D measurements. To evaluate the dimensions and functions of the right ventricle, the following projections should be used: apical-four-chamber, RV-focused apical four-chamber, parasternal long axis (PLAX), short axis (SAX), left parasternal RV inflow and subcostal views. Herein, the right ventricular outflow tract (RVOT) in the proximal segment is shown in the parasternal long axis view and in the short axis view (vascular projection). Moreover, the distal RVOT is visible in SAX directly above the pulmonary aortic annulus, while the right ventricular inflow part is imaged in the parasternal view and apical four chamber view (4CH) [1, 3].

THE ECHOCARDIOGRAPHIC ASSESSMENT OF RIGHT HEART DIMENSIONS

The recommended projection for the assessment of RV size is apical four-chamber view (4CH). However, if 4CH is solely focused on the left ventricle, significant variability of the right ventricle imaging results. Therefore, the linear dimensions and volume measurements may differ significantly in the same patient with a small ultrasound transducer rotation. Estimation of right ventricular dimensions is best obtained from a RV-focused apical four-chamber view. Care should be taken to visualize the entire free wall of the RV and to depict the LV apex in the central part of the imaging surface in order to obtain the largest RV basal diameter and prevent its shortening. From this projection, it is possible to measure tricuspid annular size and compare the RV dimension to the LV dimension. Basal RV linear dimension >41 mm and mid-cavity RV linear dimension >35 mm in RV-oriented projection indicates RV extension. The RV longitudinal dimension due to its high variability is not recommended for evaluation of RV size.

RV imaging is complemented by the subcostal view from which we measure the thickness of the RV front wall. Here, this measurement should be made at the top of the R wave and the correct value is up to 5 mm. However, this valuation can be significantly imprecise due to significant trabeculations of the RV muscle [3]. Herein, as a result of RV pressure overload in pulmonary hypertension, the cavity is enlarged and the interventricular septum (IVS) flattens, this is the so-called paradoxical motion of IVC. The degree of IVS flattening and LV compression reflects the eccentricity index (EI). This index is the quotient of LV short axis dimension measured parallel to IVS and perpendicular to IVS in systole and diastole, respectively. Normally, this index is about 1, but under RV pressure overload, the EI increases mainly in contraction. The size of the RA is measured from a 4CH projection from which we can determine its linear dimensions, areas and volumes. RA volumes measurements seems to be more accurate and robust for assessing RA size than linear dimensions. The ESC Guidelines for Diagnosis and Treatment of Pulmonary Hypertension include an RA area >18 cm² as one of echocardiographic variables suggestive of PH [1-3].

RV SYSTOLIC FUNCTION ASSESSMENT

The right myocardial performance index (RIMP), or Tei index, provides an indirect assessment of both systolic and diastolic RV function. When estimating RIMP, the isovolumic contraction time (IVCT), the isovolumic relaxation time (IVRT) and RV ejection time (RVET) should be measured (formula: Tei=IVCT+IVRT/RVET). RIMP can be assessed by way of two methods. The first method uses tissue Doppler echocardiography (TDE) to record tricuspid annular motion. This method allows performing measurements in one projection, during one heart cycle, which creates less risk of errors. The second method using pulsed wave Doppler (PW) to assess tricuspid inflow and ejection through the pulmonary valve. It requires measurements in two different projections, in two different heart cycles. RIMP may be falsely underestimated in conditions associated with elevated pressure in RA when IVRT is shortened. RIMP >0.43 with Doppler PW and >0.54 with DTI indicate right ventricular dysfunction [1].

Tricuspid annulus plane systolic excursion (TAPSE) is an easy to obtain and repeatable parameter indicating RV longitudinal function. This parameter depends on the longitudinal fiber function of the RV, and it effectively reflects the global RV systolic function. TAPSE also correlates well with other parameters used in estimating RV global systolic function. Among these are: 2D echocardiographic RV FAC and 2D echocardiographic EF. The measurement is performed from a 4CH M-mode projection through the lateral part of the tricuspid annular, with optimal alignment of the cross-sectional plane. As a one-dimensional examination, it depends on the position of the transducer, so TAPSE may overestimate or underestimate the RV function. TAPSE <17 mm indicates RV systolic dysfunction [1, 5].

Fractional area change (FAC) is an indicator to evaluate the global RV systolic function. Estimation of the right ventricular ejection fraction in 2D is not possible. Therefore, an indirect method is used to assess the percentage change of RV cross-sectional area change during systole and diastole in a 4CH projection. It is important that the entire RV, including the apex and free wall should be imaged during systole and diastole. When outlining the RV, it is crucial to incorporate the trabeculae into the RV cavity. RV FAC <35% indicates RV systolic dysfunction [1].

DTI-derived tricuspid lateral annular systolic velocity (S’) defines the systolic function of the longitudinal fibres. This method is easy to measure, and is reliable and repeat-
able. Furthermore, it has been shown to be well correlated with other RV systolic function parameters. S’ is measured from a 4CH projection. It is important to keep the pulsed Doppler gate parallel to the direction of myocardium movement, in the basement segment of the free RV wall. This method has been validated against scintigraphic evaluation of the ejection fraction. The limitations of this method include the influence of heart movement on the result and dependence on the angle of the Doppler beam measurement. In patients with pulmonary hypertension, this method can be used to monitor the effectiveness of therapy and to estimate the risk [3,12]. An S’ velocity <9.5 cm/s indicates RV systolic dysfunction [1].

Longitudinal Strain, i.e. the percentage of systolic shortening of the myocardium and strain rate, i.e. the velocity of this strain generates useful parameters for estimating global and regional systolic function of the heart cavities. RV longitudinal strain is less disturbed by heart movement, but depends on the RV filling conditions, as well as the RV dimension and shape. RV longitudinal strain is measured with the RV-focused four-chamber view. RV speckle-tracking strain is affected by imaging quality, reverberation artifacts and other artifacts, as well as attenuation. Placing basal reference points too low (e.g. in the tricuspid annular) may result in false low values of basal strain. The scope of the examination should be limited to the ventricular myocardium and should exclude the pericardium. This may be difficult due to the thinner RV wall. GLS is a parameter borrowed from LV function measuring, as existing GLS measurement software was originally designed for LV and later adapted to RV. Since the contraction of the free RV wall mainly occurs in the longitudinal direction, for RV, this parameter is only marked in the longitudinal direction. The RV GLS usually refers to either the average value for the RV free wall and septal segments or to the RV free wall segments separately. According to studies, peak global longitudinal RV strain excluding IVS, has a prognostic value in various diseases affecting right heart function, such as pulmonary hypertension. Global longitudinal RV free wall strain > -20% (i.e. <20% of absolute value) is considered abnormal. Two-dimensional STE-derived strain, especially of free wall RV, seems to be a repeatable and feasible parameter in clinical practice. This method has been validated against the assessment of the ejection fraction by magnetic resonance imaging (MRI). The advantage of this method is also the lack of dependence on the angle of incidence of the doppler beam. Due to the need to obtain data from larger studies conducted on different software, there are currently no recommended standards for global and regional RV strain and strain rate [1-8].

Three-dimensional echocardiography enables RV volume measurements, thus overcoming the limitations of 2DE echocardiography. Recommendations for 3D RV imaging include relevant guidelines issued by EAE and ASE. Although 3D echocardiography is a technical challenge, especially in patients with poor imaging quality and significant RV enlargement, we can use it to estimate RV end-diastolic volume (EDV), end-systolic volume (ESV) and RV EF. Current data give upper standard limits for RV EDVs at 87 mL/m² for men, 74 mL/m² for women, and RV ESVs at 44 mL/m² for men and 36 mL/m² for women. However, it is noted that these data need to be verified on a larger study group. Three-dimensional RV EF evaluates the global RV systolic activity. The 3D assessment was extensively validated via MRI. Volumetric semiautomated border detection is a recommended method for assessing RV EF. The limitations of the 3D RV EF estimation include load dependence, bad sound window and irregular heart rate. RV EF is slightly larger in women than in men due to smaller ventricular volumes. An EF valuation of RV by means of the 3D method that is less than 45%, suggests systolic dysfunction [1, 9-11].

**RV DIASTOLIC FUNCTION ASSESSMENT**

The cause of diastolic dysfunction of RV is myocardial fibrosis. This increases wall stiffness and thus impairs myocardial relaxation. Pulmonary hypertension is one of the conditions associated with RV diastolic dysfunction. When assessing the diastolic function, we measure the inflow through the tricuspid valve using a 4CH projection pulse Doppler. This dye by inserting a doppler gate at the top of the tricuspid valve leaflets, parallel to the direction of flowing blood. The measurement should be taken at the top of the exhalation. Using a tissue Doppler, we then measure the diastolic velocity of the myocardium (e’ and a’), placing the doppler gate in the basal segment of the free RV wall. In addition, we assess the inflow from the hepatic vein and estimate the pressure in the right atrium and its dimension. Therein, E/A and E/e’ index, early tricuspid inflow deceleration time and right atrial volume parameters are established. Based on tricuspid inflow and myocardial velocities, the following stages of RV diastolic dysfunction are distinguished:

1. impaired relaxation (when E/A<i 0.8)
2. pseudonormal filling (when E/A is between 0.8 and 2.1 and E/e’ >6)
3. restrictive RV filling (E/A>2.1 and deceleration time E<120 ms).

To measure the size of RA, it is recommended to estimate the volume by disk summation technique (Simpson) or by applying the formula $8/3\pi[(A)^2/L]$ (A: area RA, L: longitudinal RA). The measurement is made from a RV-focused 4Ch projection. The correct values are: $25\pm7$ ml/m² for men and $21\pm6$ ml/m² for women [1, 12].

**CONCLUSIONS**

Echocardiography is a very valuable tool for assessing a patient with suspected PH. This method is also used to determine the effectiveness of therapy. Indeed, it is one of the elements in estimating prognosis in these patients. Before undertaking any related procedure, it is extremely important to know the current relevant guidelines that organize the methodologies and enable a standardization of the examination.

INTRODUCTION
Hyaluronic acid (HA) was isolated in 1934 by Karl Meyer and John Palmer from the vitreous body of the bovine eye. HA is a glycosaminoglycan (GAG) from the group of structurally complex linear, anionic, hetero-polysaccharides. The name “hyaluronan” appeared in 1986 to adapt the names of polysaccharides. Further studies identified its occurrence in other organs - in the joints, skin, human umbilical cord, nervous system, epithelial, connective tissue and in the rooster comb. In addition, some bacterial strains, such as Streptococcus zooepidemicus, Escherichia coli, Bacillus subtilis, are able to produce hyaluronic acid [1-3]. Other compounds belonging to this group include: keratan sulfate I and II, heparan sulfate, chondroitin sulfate, and dermatan sulfate [4].

Hyaluronic acid is the only mucopolysaccharide that is not synthesized in the Golgi apparatus, it occurs primarily in the extracellular matrix (ECM) and is composed of a repeating disaccharide unit with a molecular weight of about 400 Da. Disaccharide units can form longer chains of up to 25,000 disaccharide units with an approximate molecular weight (MW) of 107 Da [4].

The first HA therapeutic injections were given to horses in an attempt to treat post-traumatic joint changes, which proved to be effective and has been widely used in veterinary medicine since then [5,6]. In humans, HA has been used since 1970 for the treatment of osteoarthritis (OA), and its use has recently expanded significantly, including outside orthopedic diseases [7-9].

SYNETESIS OF HA
There are three hyaluronic acid synthases that are responsible for its formation (Has1, Has2 and Has3). The synthesis takes place on the inside of the cell membrane and keeps individual polymer parts outside the cell [10]. It differs from the synthesis of other polymers because it correlates with the length of HA molecules and their viscosity. The difference between synthase products is the variable chain length of HA produced. Depending on the length of the chain, we can distinguish between small, medium and large polymers. The first two forms have pro-angiogenic and anti-apoptotic properties that stimulate heat shock protein (HSP) synthesis and are potent immunostimulants. On the other hand, large polymers act mainly in immunosuppressive and anti-angiogenic functions [11].

HA DEGRADATION
Enzymatic and chemical processes are important in HA catabolism. We distinguish the following hyaluronidases: HYAL1 - is an enzyme associated with lysosomes that breaks down HA into tetrasaccharides, HYAL2 - breaks down high molecular weight HA into 20 kDa, HYAL-3
and HYAL-4 products occur in numerous tissues, but their participation in the process the distribution of hyaluronan is insufficiently explained [10]. HYAL-4 is known to be an isoenzyme with lower specificity, in addition to hyaluronan degradation, it also has affinity for other GAGs. The group of hyaluronidas also includes PH-20 - sperm isozyme produced in the testes, also known as spreading factor and sperm adhesion molecule 1 (SPAM-1). Participates in the degradation of hyaluronan surrounding the egg - enabling penetration of the sperm, which can lead to fertilization. However, it is not clear at what point HA fragmentation changes from the extracellular process or on the cell surface into an endosomal or lysosomal process [4].

**OCCURRENCE**

HA is involved in many processes in the body. It is widely used in medicine because of its specific binding properties for a large number of water molecules. HA improves tissue hydration and resistance to mechanical damage. Interest in this compound is due to the fact that it is fully absorbable and biocompatible, which means that it is also widely available. The human body weighing 70 kg contains about 15 g of HA, which is present in many structures and tissues, including in the joints, eyes and skin. In addition to removing free radicals or rheological properties, it also plays an important role in wound healing, ovulation, fertilization, signal transduction and cancer pathophysiology [4].

**THE AIM**

The purpose of the article is to approximate the use of hyaluronic acid in orthopedics. For this purpose, selected literature was reviewed.

**REVIEW AND DISCUSSION**

Hyaluronic acid is often used in orthopedics due to its common occurrence in synovial fluid and articular cartilage. This compound is mainly administered to patients with osteoarthritis or rheumatoid arthritis. OA is a very common disease entity, especially in the elderly population, inevitably leading to disability and a significant reduction in the quality of life due to joint mobility restrictions and chronic pain [12].

Intra-articular changes that can be seen in OA include a decrease in GAG and an increase in collagen-degrading enzymes. As a result of inflammation, there is an increased production of reactive oxygen species that degrade collagen, laminins and hyaluronic acid [13]. An important aspect of the impact of HA on joint structures is the chondroprotective effect and stimulating the synthesis of proteoglycans. High molecular weight HA reduces chemotaxis and migration of inflammatory cells, leading to a reduction in inflammation, and additionally protects against free radicals [14]. Several clinical trials have shown a slowdown in OA during HA treatment [15-17]. In addition, HA has an analgesic effect in OA [14, 18].

In 2008, Balogh et al. published the results of a study aimed at assessing the absorption, distribution and elimination of orally administered HA in rats and dogs [19]. High molecular weight technetium HA labeled HA was used for this purpose to measure HA uptake by connective tissue. Scintigraphy was performed after administration of one dose of HA-labeled, which revealed a higher concentration of compound, including in joints, salivary glands, ribs. It can be assumed that the distribution of HA in the human body looks similar [19].

In one clinical study, oral administration of HA (200 mg / day) for 12 months led to a reduction in knee OA symptoms in patients aged 70 and younger, combined with exercises to strengthen the quadriceps muscle of the thigh [20]. Similar results were obtained by Nelson et al. [21] also confirmed that oral HA supplementation leads to a reduction in the severity of OA symptoms. Their observations showed that oral administration of HA leads to the regulation of inflammation detected both in serum and in SF (synovial / synovial fluid) and influences the normalization of HA circulation in SF. This suggests that the effect on the normalization of HA turnover in SF slows the progression of OA, because in preclinical models, HA turnover is associated with the severity of the disease [21].

In a randomized study, Kalman's DS et al. noted a reduced intake of acetaminophen in the study group who received oral HA. However, all authors stress that further research is needed on the impact of HA [25].

De Lucia et al. in 2020, they reviewed the systematic work comparing the effects of HA and corticosteroids (GKS) in intra-articular injection [23]. A total of 370 HA administrations were evaluated for eight different joints (shoulder, knee, ankle, foot, elbow, wrist, fingers and toes). The assessment of treatment effectiveness was performed using various scales of function and pain disorders. In summary, each study resulted in an improvement in joint function and a reduction in pain compared to baseline [23]. Saito et al. concluded that, regardless of the joint, both HA and GKS showed similar efficacy in the treatment of rheumatoid arthritis (RA) i OA [24].

There are many HA preparations on the pharmaceutical market with different molecular weights - low (500–730 kDa), intermediate (800–2000 kDa) and high (~ 6000 kDa) for IA (articular) injection [25]. The therapeutic efficacy of these products may vary depending on the origin of HA, production method, treatment protocol, viscoelasticity, molecular weight (MW) and many other properties. The half-life of HA-containing products in the joint is significantly shorter than the duration of the therapeutic effect [26]. There is no evidence in the available publications that a particular type of HA is superior to others. However, some clinical studies show that preparations with a higher MW were more effective than those with a lower MW in relieving pain associated with OA [27, 28]. Intra-articular application of HA increases the quality of synovial fluid by increasing its viscoelastic properties. The half-life of exogenous acid is very short and ranges from 2-7 days [29]. However, some researchers have shown the presence of HA in cartilage and synovium even 28 days after administration [30]. Contrary to the above results, the long-term
The articular HA preparations are characterized by good tolerance and satisfactory therapeutic effects (pain reduction), which is confirmed by randomized studies [14, 33]. A very important aspect of HA is the lack of systemic effects, which reduces the risk of drug interactions, which is particularly important in patients with OA who usually have multiple comorbidities [34]. Patients under 65 with a low OA severity are a group of patients who will definitely feel the beneficial effect of HA viscosupplementation [35]. HA can be recommended for both preventive and therapeutic use of IA as an anti-inflammatory agent, reducing the severity of symptoms and modifying the course of the disease [15-17].

RECOMMENDATIONS FOR USING HA IN OA
Currently, the positions of specialist groups are divided as to the use of hyaluronic acid in the treatment of OA. According to some societies, HA is not recommended as a reliable method of treating degenerative joint changes. AAOS (American Academy of Orthopedic Surgeons) in recommendations does not recommend the use of hyaluronic acids in the treatment of knee degenerative changes [36]. ACR (American College of Rheumatology) also does not recommend the use of hyaluronic acid in the treatment of knee and hip degenerative disease [37]. However, the international organization Cochrane states that there is evidence of positive effects of haialuronic acid in degenerative changes in the knee joints [38]. OARSI (Osteoarthritis Research Society International) recommends the use of hyaluronic acid for intra-articular injection in the knee, hip and polyarticular OA [39]. EUROVISCO (European Viscosupplementation Consensus Group) also recommends the use of hyaluronic acid in osteoarthritis. However, recommendations on HA viscosupplementation were divided taking into account the strength of the recommendations on a 1-9 scale:

- It is recommended to collect synovial fluid prior to injection for bacteriological examination when administering HA to any joint (recommendation 9).
- It is recommended to follow the dosing schedule - the number of HA injections and the interval between injections - as demonstrated in controlled randomized studies regardless of the joint to be treated (strength of recommendation 8).
- It is recommended to administer HA to the knee by the lateral patellofemoral route (strength of recommendation 9).
- It is recommended to administer HA under fluoroscopy or ultrasound control to the hip (recommendation strength 9), ankle (recommendation strength 8), shoulder (recommendation strength 8), metacarpal I (recommendation strength 8), and to the temporomandibular joint (strength of recommendation 8).
- Injections with the help of ultrasound on fluoroscopy are recommended (strength of recommendation 9) [40].

CONCLUSION
The impact of the hyaluronic acid used for delivery still raises controversy in the orthopedic circle, but many years of research prove the beneficial effects of this type of injection into joints in the treatment of degenerative changes. The studies cited above show the benefits of administering HA to OA patients, especially regarding the reduction of pain experienced by patients. Some results also suggest improving a small degree of joint mobility, but this may be due to a reduction in the pain component felt. HA monotherapy does not lead to the regeneration of joint surfaces, however, it contributes to the reduction of inflammation in OA and better nutrition of the remaining articular cartilage. Indirectly, the beneficial effect of HA in OA also consists in reducing the amount of nonsteroidal anti-inflammatory drugs taken by patients. Intra-articular injection of HA shows a low risk of systemic and local adverse effects when administered under aseptic conditions and with proper administration. Nevertheless, local inflammatory or allergic reactions occur, which, however, usually do not require invasive methods of treatment. The issue of recommending HA administration in osteoarthritis is still ambiguous, and the decision to use this type of therapy as supportive therapy for OA should be made in consultation with the patient.

INTRODUCTION
Despite several dozen years of progress in surgical techniques, as well as constant development of accompanying methods of spinal protection, ischemic spinal cord injury with subsequent paresis or paraparesis is still one of the most serious complications of both open and closed surgical treatment of aortic aneurysms. Ischemic complications of the spinal cord occur immediately after the procedure, when the patient wakes up with a neurological deficit (according to some authors within the first day after the procedure) or in a deferred manner. In the case of open surgery, immediate damage is more common, in the case of endovascular surgery - deferred. Factors such as low blood pressure, arrhythmias, cardiovascular failure, sepsis and anemia due to anemia contribute to an increased risk of delayed complications. The rehabilitation of a patient with limb paralysis as a consequence of vascular spinal injury is laborious and requires a comprehensive approach. Proper treatment and prompt intervention in the form of rehabilitation is a great therapeutic challenge.

The aim of the paper was to present the importance of the ischemic injuries of spinal cord following aortic stent graft implantation through a case report.

KEY WORDS: ischemic spinal cord injury, aneurysm, aorta, graft

ABDOMINAL AORTIC ANEURYSMS (AAA)
The incidence of abdominal aortic aneurysms increases with age [3]. In addition to age, risk factors for the development of an aneurysm in this area include male sex, smoking [4-8] hypercholesterolemia and hypertension [5, 9, 10] as well as family history of the disease. It is assumed that the risk of abdominal aortic aneurysm increases by 6% for 10 years after exceeding the age of 65 [11]. In animal models, the association of initiation and development of abdominal aortic aneurysms with inflammatory processes is noteworthy. This is confirmed by human studies [12, 13]. Also, diseases associated with a high inflammatory response such as asthma or psoriasis - are associated with a high percentage of abdominal aortic aneurysms [14,15]. Animal models also show the important role that the renin angiotensin system plays in the development of AAA [16]. Interestingly, the occurrence of diabetes reduces the risk of developing AAA [17], and high hemoglobin A1C levels is inversely correlated with the development of abdominal aortic aneurysms [18].

THORACIC AORTIC ANEURYSMS
Thoracic aneurysms (TAAs) are less common than those located in the lumbar region. Their incidence reaches...
ISCHEMIC SPINAL CORD INJURY FOLLOWING AORTIC STENT GRAFT IMPLANTATION - CASE STUDY

6-10 cases per 10,000 population. In contrast to lumbar aneurysms, they are approximately 20% associated with the 98 LU pacific genetic variants. Among the mutations associated with this type of aneurysms, min. mutations of fibrillin-1 (Fbn1) and changes associated with the TGF-beta receptor 99-103. This has also been confirmed by experimental animal studies. In addition to genetic factors, the development of aortic valve aortic valve is associated with the development of thoracic aortic aneurysms [19].

THORACOLUMBAR ANEURYSMS:
Thoracolumbar aneurysms (TAAA) are defined as 1.5 x dilatation of the thoracic and lumbar part of the aorta compared to its initial diameter. Most often occur in old age (average age of 66) [2]. Although lumbar and descending aortic aneurysms are more common than these, descending and thoracolumbar aneurysms are gaining in importance. This is not only related to the expansion of diagnostic options - enabling detection, but also to the permanent aging of societies. Their incidence reaches a total of over 16 cases in 10,000 men and over 9 in 10,000 cases in the female population [20]. The natural course leads to a constant widening of the aneurysm size up to the rupture of the vessel wall. TAAAs are classified according to the division proposed by Crawford [1]. The four-grade classification is based on anatomical coverage. Type 1 (25%) covers most of the descending thoracic aorta, from the left subclavian artery (LSA) to the renal arteries. Type II (29%) can start anywhere below LSA and extends to the splitting of the aorta. Type III (23%) starts below Th6 and can reach up to the diaphragm. The Crawford classification correlates with the difficulty of performing the procedure as well as the risk of complications. Type II is associated with the highest rates of death, paraplegia, renal failure and other complications [2].

SURGICAL TREATMENT
OPEN SURGICAL TREATMENT
Since the 1950s it has been the gold standard of TAAA treatment. Initially, homographs were used in the treatment, followed by vascular prostheses [21, 22]. Stanley E. Crawford began the era of modern TAAA treatment. His pioneering surgical technique resulted in a decrease in mortality during procedures from 26 to 8% and a risk of paraplegia to 16% (in a series of over 1,500 procedures performed) [2]. Modern data give mortality ranging from 6.2 to over 20% depending on the experience of the center, the surgeon conducting the procedure and the situation in which it is performed (elective or emergency surgery) [23, 24]. In the analysis of 797 planned open TAAA procedures performed in California, mortality within 1 month was 19%, within 1 year 31% [25]. The consequence of treatment is also often prolonged hospitalization and long, painstaking rehabilitation. Contraindications for open procedures are: advanced age, serious pulmonary diseases, circulatory failure, renal failure, complicated aortic morphology and a high risk of aneurysm wall rupture. In studies analyzing the consequences of endovascular procedures performed in patients disqualified from open surgery due to excessive operational risk, mortality during the first month was 4.8-5.5%, and complications in the form of permanent paraplegia in 2.7-4%) [26, 27]. This shows that endovascular procedures give results comparable to those achieved during open procedures performed in highly specialized centers, even taking into account that in the analyzed cases the most burdened disqualified patients from open procedures were taken into account.

ENDOVASCULAR SURGERY
Precursors of endovascularization were scientists from Eastern Europe, who in the 1980s provided traumatic injury to the thoracic aorta with a stentograft of their own design [28] a few years later, the same team undertook to stent an abdominal aortic aneurysm from the same access, but the attempt proved unsuccessful. This obstacle was overcome in 1991 [29]. A few years later, the procedures began to be applied successfully with regard to the thoracic aorta [30]. Since then, constant technical progress has been noted in both modernizing operational techniques and the equipment used at the time. In Poland in 1998, the first surgery to establish a stentograft was made by Professor M. Szczerbo-Trojanowska in Lublin [31]. It is a safe procedure, which does not require closing the vessel lumen and virtually no blood loss (max 200ml). Today, this is the standard procedure in the treatment of acute and chronic thoracic aortic aneurysms. This treatment eliminates the dissection site, restores normal blood flow to the tissues, protects the vessel walls and excludes the aneurysm from the bloodstream. It is also used in emergency or traumatic situations, where there is no possibility of surgical treatment because of the patient’s general health [32-34]. The main limitation in the use of endovascular procedures is the need to anchor grafts to the healthy wall of the vessel, without closing the vessels departing from the aorta. In the case of aneurysms involving the aortic orifices, special graft, fenestrated or branched models must be used [35]. In a large study evaluating the effect of TAAA treatment with branched stents. Studies conducted on 185 patients showed a good technical effect in 98%, mortality within the first month at 9% and complications in the form of vascular trauma in 6% [36].

ISCHEMIC SPINAL INJURIES
Ischemic spinal injury is a complication dramatically affecting the quality of life of patients. In addition to dramatic changes in quality of life, this complication also increases the risk of death for affected patients [37]. In a study comparing patients affected and not affected by a spinal cord injury in over 570 patients undergoing surgery for aneurysm, a significantly higher first-month mortality (23 to 8%) was observed, lower
The frequency of spinal cord vascular injuries is due to its blood supply system. The spinal cord is provided with vertebral artery branches: the anterior vertebral artery supplying the motor areas of the spinal cord and the two posterior spinal arteries supplying its sensory areas. The anterior spinal artery is supplied by segmental branches of the aorta by radicular medullary arteries. During aneurysmal surgery, many of these vessels may be lost, resulting in immediate or delayed ischemic injury. During open surgery, it is necessary to use a cross clamp to temporarily reduce blood flow to the spinal cord to allow surgery. In addition to reducing blood supply to the spinal cord, it contributes to an increase in venous pressure and cerebrospinal fluid, ultimately contributing to ischemia and the release of neurotoxic substances. Secondary restoration of circulation (revascularization) may, contrary to appearances, worsen this condition by reperfusion injury [40]. During endovascular surgery, the mechanism of injury is the segmental artery closure by a stentographer, especially in the absence of revascularization techniques available during open surgery. Mechanisms such as vascular embolization, hemodynamic destabilization with subsequent hypotension, and insufficient collateral circulation are also considered [39, 41]. Many strategies have been developed to prevent this complication from Cerebrospinal fluid drainage and permissive hypertension as binders. Security factors also include proper postoperative care with monitoring to prevent hemodynamic disorders and the operator's knowledge of not only the mechanisms of spinal perfusion but also the possibility of collateral circulation with subclavian and hypogastric artery, and thus ensuring their activity, especially for more extensive procedures and early intraoperative reperfusion of the lower limbs and pelvis. Ischemic complications of the spinal cord occur immediately after the procedure, when the patient wakes up with a neurological deficit (according to some authors within the first day after the procedure) or in a deferred manner. In the case of open surgery, immediate damage is more common, in the case of endovascular surgery - deferred [42]. Factors such as low blood pressure, arrhythmias, cardiovascular failure, and anemia due to anemia contribute to an increased risk of delayed complications. The rehabilitation of a patient with limb paralysis as a consequence of vascular spinal injury is laborious and requires a comprehensive approach. Proper treatment and prompt intervention in the form of rehabilitation is a great therapeutic challenge.

THE AIM
The aim of the paper was to present the importance of the ischemic injuries of spinal cord following aortic stent graft implantation through a case report.

A CASE REPORT
A 66-year-old patient was admitted to the Vascular Surgery Department of the Independent Clinical Hospital No. 4 in Lublin due to an aneurysm just above the T-Branch stent graft implanted in May 2019 due to dissection of the thoracic-abdominal aorta involving the visceral and renal vessels. After surgery in 2019, a complication of generalized sepsis occurred. In 1999, the patient underwent laryngectomy due to larynx cancer. In February 2010, based on the clinical picture and angiography, the patient was qualified for re-implantation of the stent graft due to the progressive aortic dissection above the prosthesis. In addition, the patient suffered from hypertension and gout. He was in full logical contact during the admission to the ward. The functional condition was assessed as very good. Before the surgery, in the initial functional assessment (balance and gait assessment - Tinnetti scale) a maximum of 10 points was obtained (full physical fitness, independence and no risk of falls). In the Barthel scale the maximum of 100 points was obtained, indicating complete independence in everyday life activities. The surgery was carried out correctly. In the postoperative period, complications in the form of deep flaccid paralysis of the left lower limb and deep paresis of the right lower limb occurred. In the following days there was a neurological and neurosurgical consultation and CT scan of the lumbar spinal and thoracic spine (Fig.1). The study showed degenerative changes of the spine, protrusion of the L4/5 disc, no signs of bleeding into the spinal canal. The clinical picture supported vascular spinal cord injury in the area of anterior spinal artery vascularisation. In the neurological assessment a negative Babinski reflex, no tendon reflexes, no pain sensation were found, with a untouched skin sensation. In the following days the patient was qualified and transferred to the Department of Neurological Rehabilitation in order to continue treatment and rehabilitation. Upon admission to the Rehabilitation Ward the patient was lying down, unable to sit down on his own, barely maintained a sitting position with his legs down outside the bed when seated passively. On the Barthel scale 15 points was obtained so the patient's condition was assessed as “very severe” (required help in most everyday activities). On the Tinnetti scale, he scored 0 points. In Lovett muscle strength assessment, the lower left limb was rated 0 - no movement, there was a trace of movement in lower right limb in the hip and knee flexors as well as a trace of knee extension and a trace of flexion and extension in the ankle (1+ in Lovett scale). From the first day after admission, a rehabilitation program was performed included: active exercises with upper limb resistance, active and passive exercises of the right lower limb, exercises according to neurodevelopmental methods (PNF), isometric exercises of active muscle groups and gradual passive uprighting (Fig.2). Due to the treatment of thrombosis in the left lower limb, passive exercises of that limb were contraindicated until the end of treatment. Active standing and learning of motion-related activities began after obtaining...

medical permission. Then the scope of physiotherapy was expanded to equilibrium exercises and proprioception exercises in high positions, such as sitting and standing (Fig.3). After a period of 16 weeks of rehabilitation in the ward, the patient obtained a significant improvement in the strength of the muscles of the lower right limb (hip flexors 4, knee flexors 4, ankle flexors 3 in Lovett scale). The left lower limb was still functionally weaker (hip flexors 3, knee flexors 3, ankle flexors 2 in Lovett scale). The stabilization of the torso improved significantly, which enabled the patient to sit and stand independently with the help of a high walker or another person (Fig. 4). To protect the feet while walking, orthopedic equipment in the form of ankle drop foot orthosis was used (Fig. 5). When performing self-service activities, e.g. dressing, toilet, he no longer required the assistance of “third parties. On the Barthel scale he obtained 65 points. After 18 weeks of rehabilitation, the patient is able to cover a distance of 150 meters, still supplied with orthosis and high walker. He describes his state as satisfying.

CONCLUSIONS
Factors increasing the risk of developing aortic aneurysm include: age over 55, male gender, family history of aneurysms, smoking, atherosclerosis, chronic obstructive pulmonary disease (COPD), hypertension, high blood cholesterol, ischemic heart disease.

Intravascular prosthesis insertion is a method increasingly used all over the world, enabling safe interference and repair of damaged vessels. Endovascular treatment allows therapy at an early stage of disease development. Complications of endovascular treatment include: leakage of blood into the aneurysmal sac, migration of the stent graft, stent graft breakdown or stent graft thrombosis [43] Jargielo. A sharp increase in blood pressure during the stentogram expansion, poor placement associated with advanced atherosclerosis, can also cause a thrombus within the stentogram or lead to a fracture. Endovascular complications requiring long-term and comprehensive rehabilitation are stroke (4-6.7%) or permanent or transient spinal cord stroke (0-3%) [44, 43]. In order to avoid the above complications after surgery are used: the shortest aortic clamping time, not exceeding 60 minutes, avoiding drops in blood pressure during the procedure, monitoring of cerebrospinal fluid pressure, and if necessary cooling through epidural infusions of saline and the use of opioid receptor antagonists [44, 45].

Effective treatment of postoperative complications of aneurysms and aortic wall dysfunction as well as rapid recovery of the patient from before surgery depends on early and comprehensive rehabilitation. Physiotherapy should be carried out in the first postoperative days and carried out in a safe manner for the patient, under full medical supervision. Then we have a better chance of returning the patient to optimal mobility and independence in life.
