INTRODUCTION
Unfortunately, timely diagnosis of liver disease in newborn infants remains an urgent problem today, since various disorders of the liver often have virtually the same initial clinical features, or they generally have a latent course. Since liver dysfunction is progressive, early detection of pathology allows time to initiate appropriate therapeutic measures and significantly improve the prognosis [1]. The role of the pathomorphologist in addressing common problems of liver disease in children is likely to change in the future with the progress of molecular genetic revolution. However, even when biochemical, microbiological, and immunological laboratories already provide essential diagnostic information, an informed morphological interpretation of liver disease in children continues to be an important method of diagnosis [2]. Primary interpretation of liver disease in children may occur through clinical and laboratory data, but differential diagnosis and prognosis of liver disease require more accurate morphological data, and this primarily concerns the assessment of the stromal-parenchymal component of the liver [3]. In order to correctly and reliably evaluate the quality of the stromal-parenchymatous component of the liver of a newborn baby and to correctly interpret the presence or absence of liver pathology, information on the normal rates of stroma and liver parenchyma in healthy newborn infants should be compared. The study of world and national resources showed the absence of such data, so there is a need to provide such information to the scientific community and practitioners to optimize diagnosis of liver disease in children.

THE AIM
Study of morphometric parameters of stromal-parenchymatous component of liver of healthy full-term newborns from healthy mothers with physiological course of pregnancy.

MATERIALS AND METHODS
Investigated 45 biopsies of the liver tissue of healthy term infants of 37-40 weeks gestational age born to healthy
mothers with physiological pregnancy and died due to severe head injury, or premature detachment of normally situated placenta during delivery; life expectancy in all cases did not exceed 24 hours. The autopsy material research was conducted according to the requirements of «Instruction on conducting autopsies» (Ministry of Health of Ukraine order № 6 from 17.01.1995); the requirements, norms and standard provisions on ethics of the Ministry of Health of Ukraine № 690 from 23.09.2009 p.; «The procedure for the removal of biological objects from the dead, whose bodies are subject to forensic and pathoanatomical research, for scientific purposes» (2018). The material was collected during the period from 2010 to 2018 in pathoanatomical department of Kharkiv Regional Perinatal Center.

For morphological study liver slices were fixed in 10% solution of neutral formalin and then subjected to standard processing through liquid Nikiforov (96% alcohol and diethyl ether in the ratio 1: 1), chloroform and then paraffinization.

The recived blocks were sliced intro pieces of 4–5 μm thick by Microm HM - 340 microtome. The obtained samples were coloured with hematoxylin and eosin as well as using method Mallory.

Regenerative activity of liver parenchyma was evaluated by the number of binucleated and mononucleated hepatocytes. The number of binucleated / mononucleated hepatocytes was calculated using the Avtandilov microscopic morphometric grid, which consisted of 100 equidistant points and was inserted into the microscope eyepiece with × 200 magnification of the microscope. The number of dots that occurred in single and dual hepatocytes was counted. Each sample was studied in 10 randomly selected fields of view, and the data were calculated and presented as a percentage [4]. Also, the calculated rate of binucleated / mononucleated hepatocytes (RBMH) by the formula:

\[
\text{RBMH} = \frac{\text{Number Of Binuclear Hepatocytes}}{\text{Number Of Mononuclear Hepatocytes}} \times 100
\]

For morphometric assessment of the stromal, parenchymatous, vascular and biliary components of the liver, was also used Avtandilov microscopic morphometric grid, which consisted of 100 equidistant points and was inserted into the microscope eyepiece with × 200 magnification of the microscope. The number of dots that occurred in single and dual hepatocytes was counted. Each sample was examined in 10 randomly selected fields of view, and the data were calculated and presented as a percentage. Also, stromal-parenchymal index (SPI) was calculated by the formula:

\[
\text{SPI} = \frac{\text{Stromal Index}}{\text{Parenchymal Index}}
\]

Immunohistochemical features of the components of the liver were studied using indirect immunoperoxidase method on paraffinized sample of 3-5 microns thick. In all cases, each sample was studied in 10 randomly selected fields of view, and positive signals (positive expression in the form of a brown color) were measured by Avtandilov microscopic morphometric grid, which consisted of 100 equally equidistant points was inserted into the eyepiece eyepiece with × 200 magnification of the microscope. The number of dots that occurred in the positive signal was counted, and the data were calculated and presented as a percentage. The samples were studied using a BX43 optical microscope (Olympus Corporation, Tokyo, Japan) and the expression was analyzed using a quantitative image analysis system (Image-Pro Plus 6.0; Media Cybernetics Inc., Rockville, MD, USA).

Fibronectin expression level fibronectins antibodies (mouse polyclonal; 1: 100; sc-8422; Santa Cruz Biotechnol- ogy, Inc.) were used. The blocks were heated for 60 minutes at 60 °C, deparaffinized with xylene and washed in alcohols with a decrease in their concentration. Antigens were obtained with citrate buffer (pH 6.0) in a microwave oven for 5 minutes. After being processed in 1.5% H₂O₂ at 37 °C for 30 minutes to block endogenous peroxidase activity, the samples were incubated with primary antibodies overnight at 4 °C and then incubated with secondary antibodies (PV-9002; OriGene Technologies, Inc., Beijing, China) for 30 minutes at room temperature. Finally, samples were coloured using diaminobenzidine followed by hematoxylin contrast.

To assess the level of expression of collagen type I and III collagen using antibodies against type I and III (polyclonal rabbits, 1: 600; Abcam, Cambridge, UK). The blocks were heated for 60 minutes at 60 °C, deparaffinized with xylene and washed in alcohols with decreasing concentration. The preparations were first pre-incubated in 3% H₂O₂ solution for 10 minutes at room temperature to block endogenous peroxidase activity, and then the antigen was extracted with citrate buffer (pH 6.0) in a microwave oven at 95–98 °C for 12 minutes, followed by incubation for 5 minutes at room temperature to block non-specific background staining. Then, incubated at room temperature for 30 minutes with primary rabbit polyclonal antibodies against type I and III collagen. The obtained preparations were washed four times with buffer, treated with streptavidin, peroxidase and chromogen DAB. Finally, the sections were stained using diaminobenzidine followed by hematoxylin contrast.

To assess the level of expression of type IV collagen used antibodies against type IV collagen (polyclonal mice; 1:100; Leica Biosystems, Newcastle, UK: PHM-12, UK). The blocks were heated for 60 minutes at 60 °C, deparaffinized with xylene and washed in alcohols with decreasing concentration. Antigens were obtained with citrate buffer (pH 6.0) in a microwave oven for 5 minutes and then cooled at room temperature for 20 minutes. After processing 3% solution of H₂O₂ at 37 °C for 30 minutes to block the endogenous activity of peroxidase, sections were incubated with primary antibodies overnight at 4 °C, and then incubated with secondary antibody (K-ASSAY Collagen Type IV Staining Kit, Kamiya Biomedical Company, USA) for 30 minutes at room temperature. Finally, sections were stained using diaminobenzidine followed by hematoxylin contrast.

To assess the presence of liver fibrosis, a non-invasive analysis of two biomarkers of liver fibrosis in blood APRI and FIB-4 was performed. Indicators of biomarkers of fibrosis were calculated according to officially published...
recommendations [5, 6, 7, 8] using the following formulas:

\[
\text{APRI} = \frac{\text{AST (IU/L)}}{\text{AST (ULN) (IU/L)/ Platelet Count (10^9/L)}} \times 100, \\
\]  

(1)

\[
\text{FIB-4} = \left[\frac{\text{Age (years) \times AST (IU/L)}}{\text{Platelet Count (10^9/L) \times } \sqrt{\text{ALT (IU/L)}}}\right] \\
\]  

(2)

AST – aspartate aminotransferase; AST ULN (Upper Limit of Normal) – aspartate aminotransferase (40 IU/L).

Results

In the macroscopic study liver was elastic to the touch and had excellent thin translucent capsule. On the cross section of the liver tissue was red-brown, homogeneous, with properly developed and unevenly full-blooded hepatic veins. Microscopically was observed the normal radiorna-beam structure, normal sinusoids and central veins, and a few small sites of extramedullary hematopoiesis.
Hepatocytes had slightly granular eosinophilic cytoplasm and round basophilic nucleus. The morphometric parameters of hepatocytes were as follows: mononuclear hepatocytes - 93.5 ± 7.1%, binuclear hepatocytes - 6.5 ± 1.2%, RBMH (binuclear / mononuclear hepatocytes coefficient) - 0.06 ± 0.01, hepatocytes with fat vacuoles - 0.5 ± 0.2%.

The portal stroma was developed normally and consisted with collagen fibers.

Stromal-parenchymal indices of liver were as follows: parenchyma - 74.2 ± 4.3%, stroma (including vessels and bile ducts) - 25.8 ± 2.6%, SPI (stromal-parenchymal index) - 0.34 ± 0.01.

The morphometric parameters of all components of the liver were as follows: hepatocytes - 74.2 ± 4.3%, portal tracts - 3.1 ± 0.6%, central veins - 9.3 ± 1.4%, sinusoids - 10.5 ± 1.3%, bile ducts - 2.9 ± 0.2%. Across the liver parenchyma had a moderate amount of fibronectin matrix protein in the cytoplasm of hepatocytes and in the Disse spaces along of sinusoids.

Tape I and III had moderate expression in the stroma of the portal tracts. Also, those types of collagen were detected in Disse spaces along of sinusoids in a small amount, which was documented by their weak expression.

There was a moderate amount of type IV collagen in the Disse spaces along sinusoids, which is normal major component of basal membranes.

The levels of expression of fibronectin, type I, III and IV collagens in the stromal component of the liver were as follows: fibronectin - 17.3 ± 2.5%, type I collagen - 9.7 ± 1.9%, type III collagen - 10.1 ± 0.9%, type IV collagen - 5.9 ± 0.2%.

The level of ALT in the blood of newborns averaged 12.6 ± 2.2 IU/L, AST - 21.2 ± 2.7 IU/L, platelets - 267.3 ± 22.6 × 10^9/L. The biomarkers of liver fibrosis were as follows: APRI (index) - 0.19 ± 0.01, and FIB-4 (index) - 0.022 ± 0.001.

DISCUSSION

The world literature is lock of any studies about morphometric parameters of the stromal-parenchymal component of the normal liver of healthy infants from mothers with physiological pregnancy. The resulting morphometric data stromal-parenchymatous component of a normal liver (morphometric parameters of the number of hepatocytes, portal tracts and central veins, sinusoids, bile ducts, fibronectin, collagen I, III and IV types) can be used as control group in the study of various pathological conditions of the liver of newborn children.

Liver biopsy is considered the «gold standard» for assessing the presence and severity of fatty liver and especially liver fibrosis. However, this procedure is invasive and is intended for children only in extreme cases [9]. Therefore, the scientific community has proposed two serum biomarkers APRI and FIB-4, which can reliably detect the presence and severity of liver fibrosis without the need for a traumatic liver biopsy procedure [10]. APRI and FIB-4 liver fibrosis biomarkers are simple and easy to use, and there are no complex components in formulas that required to calculate them. To calculate both biomarkers of fibrosis, it is necessary to register the ALT, AST, and platelet counts in the blood plasma (routine total blood count and hepatic metabolic panel), and for the FIB-4 biomarker, one must have the information about patient's age.

Biomarkers of liver fibrosis have been well studied in adults, however, there are lock of any studies about biomarkers of liver fibrosis in healthy newborns from healthy mothers with physiological pregnancy, so this study presents the data about APRI and FIB-4 for the first time.

CONCLUSIONS

The presented morphometric data of stromal-parenchymal component of the normal liver of healthy infants from healthy mothers with physiological pregnancy (morphometric parameters of number of hepatocytes, portal tracts and central veins, sinusoids, bile ducts, fibronectin, collagen I, III and IV types), and biomarkers of liver fibrosis APRI and FIB-4 can be used as a control group in the study of any pathological conditions in the liver of newborns.
